

Introduction to Lambda Functions

Exercises

- Describe some of the disadvantages of using functors to provide predicate functions for algorithms
 - Boilerplate code (several lines to implement a one-line function)
 - Need to invent a name for it which won't conflict with anything else ("namespace pollution")
 - Interrupts writing and reading the code (productivity)

- Explain briefly what is meant by a lambda expression
 - A lambda expression is an executable block of code that is written as a “local function” within another block of code
- Explain briefly how a lambda expression is implemented by the compiler
 - The compiler will generate a functor whose () operator contains the code from the body of the lambda expression
 - The compiler will create an instance of this functor and call it when required

- When creating a lambda expression, how do we enter
 - its name?
 - Lambda expressions are anonymous. We put [] where the name of the function would go
 - its arguments?
 - Inside (), just like a normal function

- When creating a lambda expression, how do we enter
 - its function body?
 - We write the function body inside {}, just like we would for an inline function
 - its return type?
 - This will be automatically deduced, provided the lambda function body is a single return statement (C++11)
 - This will be automatically deduced (C++14)

- Rewrite the `count_if` example to use a lambda expression instead of the `is_odd` functor
- Write a simple program to test your code
